Virginia Land Snails

*Gastrocopta riparia* Pilsbry, 1916 (not yet reported)

Family: Vertiginidae

**Identification**
Height: ~2.5mm
Width: ~1.1mm
Whorls: 5

This species is distinguished from the very similar *G. procera* by the placement of the lower palatal lamella. In *G. riparia* this "tooth" is less deeply inserted with the long axis being roughly perpendicular to the lower apertural margin, rather than parallel as in *G. procera* (Nekola & Coles, 2010).

**Ecology**
*Gastrocopta riparia* is found in decomposed leaf litter, often under dense shrub or vine thickets in damp, disturbed sites such as railroad rights-of-way, roadside verges, vacant lots, floodplains, and other scrubland habitats. It seems more tolerant of acidic conditions than *G. procera* (Nekola & Coles, 2010).

**Taxonomy**
A synonym for this animal’s name is *Gastrocopta procera* form *riparia*. Although Hubricht (1985) and Nekola & Coles (2010) attributed this taxon to Hubricht, 1975, we follow Turgeon et al. (1998) and NatureServe who attributed it to Pilsbry, 1916. Turgeon et al. (1998: 289) noted that this taxon was validly proposed by H.A. Pilsbry (1916, Man. Conchol. ser. 2, 24-65).

**Distribution**
This animal is restricted to the southeastern coastal plain, where it ranges from southern Texas across the Gulf Coast to the Albemarle-Pamlico Peninsula in eastern North Carolina.

Although *Gastrocopta riparia* has not yet been recorded from Virginia, given its nearby presence in the outer coastal plain of North Carolina, it is to be expected from the far southeastern part of the state and from the counties to the east of Chesapeake Bay.

NatureServe Global Rank: G4G5
NatureServe State Rank: none
